The Exponential Random Configuration Model

Let $c(t) \in \{0,1\}^N$ be a vector indicating which Supreme Court case has been cited at time t, where $c_i(t) = 1, i \in \{1, ..., N\}$ indicates that the ith case has been cited at time t and $c_i(t) = 0$ indicates that the ith case has not been cited at time t. Furthermore, let

$$C_t(N) = \{c(t) \in \{0, 1\}^N : c_i(t) \in \{0, 1\}\}$$

be the set of all possible citation combinations at time t. Note that the cardinality of $C_t(N)$ increases exponentially for every newly added case, which results in 2^N elements.

The probability function of the ERCM is defined as

$$P_{\theta}(c(t) \mid c(t-)) = \frac{\exp\left(\theta^T \cdot h(c(t) \mid c(t-))\right)}{\sum_{c(t)^* \in \mathcal{C}} \exp\left(\theta^T \cdot h(c(t) \mid c(t-))\right)}$$
(1)

where $c_{t-} \in \{0,1\}^{N \times (t-1)}$ is a matrix that indicates which cases have been citing in each other before time t, $\theta \in \mathbb{R}^q$ is a q-dimensional vector of parameters, $h: \mathcal{C}_t(N) \to \mathbb{R}^q$, $(t) \to (h_1(c(t)), \dots, h_q(c(t)))^T$ is a q-dimensional vector of different statistics and $\kappa(\theta) := \sum_{c(t)^* \in \mathcal{C}} \exp(\theta^T \cdot h(c(t)|c(t-)))$ is a normalization constant that ensures that (1) defines a probability function on \mathcal{C}_t .

The generative process of a model are informed by the decision regarding which network statistics $h(\cdot)$ are incorporated. We include the following statistics for the Supreme Court citation network:

$$h_{edges}: \mathcal{C}(N) \to \mathbb{R} \quad , \quad c(t) \to \sum_{i=1}^{N} c_i(t)$$

the number of citations made at time t.

$$h_{outstar}: \mathcal{C}(N) \to \mathbb{R}$$
 , $c(t) \to \sum_{i \le i}^{N} c_i(t) \cdot c_j(t) \cdot \sqrt{\frac{(t-a)(t-a-b)}{t^2}}$

the number of weighted outstars occurring at time t. We argue that it should me more likely to cite more recent cases than cases that have been decided further in the past. For the weight

$$w(a,b) := \sqrt{\frac{(t-a)(t-a-b)}{t^2}}$$

we define a and b as the elapsed time since case i and j have been introduced to the network.

$$h_{triangle} : \mathcal{C}(N) \to \mathbb{R}$$
 , $c(t) \to \sum_{j < i}^{N} c_i(t) \cdot c_j(t) \cdot c_j(t) \cdot w(a, b)$

where $c_j(t_{-i})$ indicates whether case j was cited at the time case i was introduced into the network. Just as for the outstar statistic, we include a weighting factor to favor more recent cases.

The individual entries $c_i(t)$ can be taken as a manifestation of single Bernoulli variables $C_i(t)$. This interpretation allows the following calculation regarding the

conditional distribution of $C_i(t)$:

$$\frac{P_{\theta}(C_{i}(t) = 1 \mid C_{i}(t)^{c} = c_{i}(t)^{c})}{P_{\theta}(C_{i}(t) = 0 \mid C_{i}(t)^{c} = c_{i}(t)^{c})} = \frac{P_{\theta}(C_{i}(t) = 1, C_{i}(t)^{c} = c_{i}(t)^{c})}{P_{\theta}(C_{i}(t) = 0, C_{i}(t)^{c} = c_{i}(t)^{c})}$$

$$= \frac{P_{\theta}(C(t) = c_{i}^{+}(t))}{P_{\theta}(C(t) = c_{i}^{-}(t))}$$

$$= \frac{\exp(\theta^{T} \cdot h(c_{i}^{+}(t) \mid c(t-)))}{\exp(\theta^{T} \cdot h(c_{i}^{-}(t) \mid c(t-)))}$$

$$= \exp(\theta^{T} \cdot (h(c_{i}^{+}(t) \mid c(t-)) - h(c_{i}^{-}(t) \mid c(t-)))$$

This implies the following equation:

$$logit(P_{\theta}(C_i(t) = 1 \mid C_i(t)^c = c_i(t)^c)) = \theta^T \cdot (h(c_i^+(t) \mid c(t-)) - h(c_i^-(t) \mid c(t-)))$$
(2)

In the equation above the following notations were used:

- $c_i^+(t)$ emerges from c(t), while assuming $c_i(t) = 1$
- $c_i^-(t)$ emerges from c(t), while assuming $c_i(t) = 0$
- The condition $C_i(t)^c = c_i(t)^c$ is short for: $C_j(t) = c_j(t)$ for all $j \in \{1, ..., N\}$ with $i \neq j$
- The expression $(\Delta c_i)(t) := h(c_i^+(t) \mid c(t-)) h(c_i^-(t))$ is called the *change* statistic. The kth component of $(\Delta c_i)(t)$ captures the difference between citation networks $c_i^+(t)$ and $c_i^-(t)$ on the kth integrated statistic in the model

Estimation

Maximum Pseudo-Likelihood Estimator

One can assume that the dyads are independent of each other, which means that the random variables $C_i(t)$ inside the random vector C(t) are independent of each other. In this case, the equation (2) reduces to

$$logit(P_{\theta}(C_i(t) = 1)) = \theta^T \cdot (\Delta c_i)(t)$$

This corresponds with the logistic regression approach, where the observations of the dependent variables are simply edge values of the observed citation vector, and the observations of the covariate values are given as the scores of every single change statistic. Therefore, the resulting likelihood function is of the following form:

$$\operatorname{lik}(\theta) = P_{\theta}(C(t) = c(t)) = \prod_{i} \frac{\exp\left(\theta^{T} \Delta(c_{i})(t)\right)}{1 + \exp\left(\theta^{T} \Delta(c_{i})(t)\right)}$$
(3)

Maximum Likelihood Estimator

The more rigorous technique is to estimate the parameters directly with the loglikelihood function derived from (1), which has the following form:

$$loglik(\theta) = \theta^{T} \cdot h(c(t)|c(t-)) - log(\kappa(\theta))$$
(4)

The problem resulting from estimating the parameters with (4) is that the term

$$\kappa(\theta) := \sum_{c(t)^* \in \mathcal{C}(N)} \exp(\theta^T \cdot h(c(t)^* | c(t-)))$$

which sums up the weighted statistics of all possible binar vectors of length N, has to be evaluated.

MCMC
